Dedication

To

The lights of my life

Father & Mother

The lights of my eyes

Brothers, Sisters and My Friends

*All faithful hearts who helped me
in the journey of my life.*

Ahmed

Acknowledgement

First of all I thank the Almighty *Allah*, whose Grace enabled me to continue this work and overcome all difficulties and our prophet *Muhammad* (peace and blessings of Allah be upon him) who invites us to science and knowledge.

I would like to express my sincere appreciation and deep gratitude to my supervisors, **Prof. Dr. Nabeel A. Bakr** and **Prof. Dr. Iftikhar M. Ali** for suggesting the topic of this thesis, guidance, suggestions and continuous encouragement throughout the research work

I would like to express my profound gratitude to **Prof. Dr. Sabah A. Salman** for his kind cooperation and constant support. I am highly indebted to **Assist. Prof Dr. Ziad T. Khodair** for his constant encouragement throughout my Ph.D. study in the Department of Physics, College of Science, University of Diyala.

Special thanks are extended to the University of Diyala, College of Science, specially The dean of College of Science, **Prof. Dr. Tahseen H. Mubarak** and the head of the department, **Dr. Jasim M. Mansoor** and all the Staff of the Department of Physics for their assistance.

I would also like to thank the staff of the Library of College of Science(**Adnan and Raafat**), who continued to provide excellent service, tireless support and scientific resources to all students.

I do not forget to thank **Assist. Prof. Dr. Issam M. Ibrahim** (Baghdad University), and Physics Department staff for their support.

I am grateful to the staff of thin film laboratory and my colleagues at Physics Dept. College of Science, University of Baghdad, **Marwan, Abeer, Suhaad and Masar.**

My greatest indebtedness goes to my **Father, Mother and Brothers** for their valuable advice, and to my Friends (**Aws, Wisam, Ali, Adnan, Abo Ayman, Mohammed Alazawi, Waleed, Ibrahim, Haidar, Marwan, Bashar, Kadhim Al-Jumaily, Anwar and Sufian**) for their endless support.

Supervisor Certification

We certify that this thesis entitled "**Synthesis and Characterization of Inorganic – Polyaniline Hybrid Nanostructures for Sensing Applications**" for the student (**Ahmed Mohammed Shano**), was prepared under our supervisions at the Department of Physics, College of Science, University of Diyala in partial fulfillment of requirements needed to award the degree of **Doctor of Philosophy (Ph.D.) in Physics**.

Signature: N. A. Bakr

Name: **Dr. Nabeel A. Bakr**

Scientific Degree: Professor

Address: College of Science,

University of Diyala

Date: 25 / 9 / 2018

Signature: Iftikhar M. Ali

Name: **Dr. Iftikhar M. Ali**

Scientific Degree: Professor

Address College of Science

University of Baghdad

Date: 25 / 9 / 2018

In view of the available recommendations, we forward this thesis for debate by the examination committee.

Abstract

In this study, PANi NFs and metal oxides nanostructures [tin oxide (SnO_2) and copper oxide (CuO)] have successfully synthesized by using hydrothermal method and depositing PANi NFs, SnO_2 and CuO and their composites on silicon and glass substrates by spin coating technique at room temperature with thickness of about 325 nm. The structural, surface morphological, optical, electrical, photoconductivity and gas sensing properties have been investigated for Inorganic – Polyaniline films. The XRD results showed that PANi films have crystalline nature, SnO_2 and PANi/ SnO_2 nanostructure composite are polycrystalline in nature with tetragonal structure, CuO and PANi/ CuO nanostructure composite are polycrystalline in nature with Monoclinic structure, The crystallite size is estimated by Scherrer formula and W-H analyses and it is found that it increases as the concentration ratio of SnO_2 and CuO increasing. The FESEM images of Polyaniline clearly indicate that the polymer possesses nanofiber like structure, where's the SnO_2 and CuO films have cauliflower like and regular shapes respectively. The surface morphology of composites are nanofiber capped with inorganic material which are SnO_2 and CuO as core-shell structure. The optical properties show that the energy gap follows allowed direct electronic transition calculated using Tauc's equation and it is noticed that the band gap value decreases as the SnO_2 , CuO ratios increases. PL showed that peaks intensity increases as the concentration of SnO_2 and CuO increases. The electrical properties include Resistance–Temperature Characteristic, D.C. electric conductivity and Hall effect measurements. The resistance of the films decreases as the temperature increased which shows a semiconductor behavior and activation energies and electrical conductivity (σ_{RT}) are decreases with increasing

of addition of inorganic semiconductors into PANi NFs. The results of Hall coefficient showed p-type semiconductor behavior for all films except that for pure SnO₂ films which is n-type. The built-in potential (V_{bi}) increases with increasing by addition of inorganic composites into polymer matrix. The photoconductivity properties, in current-voltage (I-V) characteristics, the value of ideality factor and tunneling factor increase with increasing by adding of inorganic semiconductors into polymer matrix, the responsivity, G%, D and D* increase with increases of SnO₂ and CuO nanostructures ratio except NEP is decreases, and the current -time (I-t) characteristics investigate that the response had square pulse for UV-Vis light region that means fast response for all films. The sensitivity to H₂S gas increased with increases of operating temperatures and SnO₂ and CuO concentration. The maximum sensitivity to H₂S gas was observed to nanocomposites PANi/CuO films at high amount of CuO and found to be 260 % at ($T_o = 200\text{ }^\circ\text{C}$). The response and recovery time increased with increase in operating temperature and SnO₂ and CuO concentration and the nanocomposites PANi/CuO films at concentration 3mL from CuO exhibits a fast response speed (0.753s) with recovery time (0.787s) at (30°C), while the slow response speed was observed for 7mL CuO (0.921s) with recovery time of (0.857s).

α	Absorption Coefficient	cm^{-1}
A' and γ	Constants Depending on Properties of Conduction and Valance Bands	
ν	Frequency	Hz
K_e	Wave Vector of Transmitted Electron	cm^{-1}
\vec{K}_{ph}	Photon Wave Vector	cm^{-1}
\vec{K}	Wave Vector	cm^{-1}
M	The Molar Concentration	mol/L
M_{wt}	Molecular Weight	g/mol
V	Volume of Distilled Water	mL
a	Lattice Constant	Å
b	Lattice Constant	Å
c	Lattice Constant	Å
FWHM(β)	Full Width at Half Maximum	rad
D_{av}	Average Crystallite Size	nm
d_{hkl}	Interplanner Spacing	Å
S	Micro Strain	%
λ	Wavelength	Å
N_0	Number of Grains Per Unit Area	cm^{-2}
δ	Dislocation Density	Line. cm^{-2}
E_g	Energy Band Gap	eV

E_u	Urbach Energy	meV
E_d	Dispersion Energy	eV
E_v	Valence Band Energy	eV
E_c	Conduction Band Energy	eV
E_p	Assistant Phonon Energy	eV
λ_c	Cut off Wavelength	nm
h	Planck's Constant	J.s
J	Current Density	A/cm ²
T	Transmittance	
A	Absorbance	
μ_n	The Mobility of Electron	cm ² /V.s
μ_p	The Mobility of Hole	cm ² /V.s
τ	Carrier's Lifetime	s
V_d	The Drift Velocity	m/s
m^*	The Effective Mass	g
Σ	The Electrical Conductivity	($\Omega.cm$) ⁻¹
σ_o	The Minimum Electrical Conductivity at 0 K	($\Omega.cm$) ⁻¹
E_a	The Activation Energy	eV
B	Magnetic Field	Tesla
R_H	The Hall Coefficient	cm ³ /C
V_H	The Hall Voltage	Volt
μ_H	The Hall Mobility	cm ² /V.s
V_{bi}	The Built - In Voltage	Volt
q or e	The Electron Charge	C
n	The Carrier Concentration	cm ⁻³
p	The Hole Concentration	cm ⁻³
I_o	The Saturation Current	A

A^*	The Effective Richardson Constant	$A.m^{-2}K^{-2}$
T	The Absolute Temperature	K
Φ_B	The Barrier Height	eV
n	The Ideality Factor	
A_t	Tunneling Constant	
V_F	The Forward Bias Voltage	Volt
I_F	The Forward Bias Current	A
τ_r	Rise Time	s
τ_f	Fall Time	s
Δf	Bandwidth	Hz
R_λ	Responsivity	A/W
$J_{ph}(\lambda)$	The Photocurrent Density From the Tested Detector	A/cm^2
$P_{inc}(\lambda)$	The Incident Power Density	$\mu w/cm$
c	The Speed Of Light	m/s
NEP	Noise-Equivalent Power	W
I_n	I_n Noise Current	A
R_d	Dark Resistance	Ω
D	Detectivity	W^{-1}
D^*	Specific Detectivity	$(cm Hz^{1/2} W^{-1})$.
S	Sensitivity	
R_a & R_g	R_g The Electrical Resistance of the Film in The Air and Electrical Resistance	Ω

VOCs	The Detection of Volatile Organic Compounds
SDS	Sodium Dodecyl Sulphate

Chapter One

*Introduction
and Basic
Concept*

1.1 Introduction

One goal of today's technology is the miniaturization of the electronic, actuating, sensing, and optical devices and their components; hence, nanotechnology is an advanced technology that has received a lot of attention from the world of the science and industry for its ability to make use of the unique properties of nanosized materials. Nanotechnology is capable of manipulating and controlling material structures at the nano level (a nanometer equals to one millionth of a millimeter) and offering unprecedented functions and excellent material properties [1]. Nanotechnology can be defined as the ability to work near the molecular level, atom by atom, to create large structures with fundamentally new properties and functions. Nanotechnology can be described as the precision-creation and precision control of atomic-scale matter [2]. It offers new design, characterization, production, and application of systems, devices and materials at the nanometer scale. It is an interesting and vibrant field of research. Their roots can be traced back to Feynman's famous lecture in 1959, in which he suggested that for entities with nanoscopic dimensions new physical phenomena should arise [3]. The nanoscale dimension is important because quantum mechanical properties of electronics, photons, and atoms are evident at this scale. Its structures permit the control of fundamental properties of materials without changing the materials' chemical status. Nanostructures, such as nanophotonic devices, nanowires, carbon nanotubes, plasmonic devices, among others, are planned to be more powerful communication systems and quantum computers [4].

Nanoscale structures are used to study a range of interesting effects that occur when electrons are confined to very small geometries. For example, the quantized electron wave states in a nanostructure are reflected in measurements of electron transport through the structure. Electron transport experiments have been used to investigate many different

nanostructures. As the scale of materials is reduced to nanometers, the tendency of surfaces to minimize their free energy may drive structural changes [5].

1.2 The Physics of Low Dimensional Material

Over the last few years, advances in solid state physics have been characterized by a change from bulk crystal to a very small at least one of their three dimensions. Semiconductor nanocrystals are the subject of a rapidly developing field. It can be defined as crystals with dimensions ranging from 1-100 nm; above this size, they are termed microcrystals. When the dimensions of a solid are reduced from a large size to the size of the characteristic lengths of electrons i.e. de Broglie wavelength λ_B , coherence length and localization length then the particles behave wave-like and the crystal size becomes smaller leading to the semiconductor energy levels to be more separated from each other and the effective band gap to increase, therefore new physical properties due to quantum effect is observed, such as: quantum conductance oscillations, quantum Hall effects, resonant tunneling single electron transport, etc. These properties are necessary to build nanostructure semiconductor heterojunction, super lattice, etc. [6].

Low dimensions materials are classified according to the number of dimensions in nanometer size into three types [7]: **Quantum wells (2D)**, **Quantum wires (1D)**, and **Quantum dots (0D)**.

1.3 Conducting polymers

The term “polymer” comes from “poly”, which means many, and “mer”, which means units. Conducting polymers are a prospective class of new materials that combine solubility, process ability and flexibility of plastics with electrical and optical properties of metals and semiconductors [8].

1.4 Conjugated Polymer

A polymer chain is characterized by an alternation of saturated and unsaturated carbon-carbon bonds, leading to the presence of non-localized electrons $\{\pi\text{-electrons}\}$ [9]. The conjugated structure with alternating single and double bonds or conjugated segment coupled with atoms providing P-orbital for a continuous orbital overlap seem to be necessary for polymers to become electrically conducting. This is due to the conjugated structure not only provides a continuous conduction path through the P-orbital overlapping along the polymer backbone but also facilitates the generation of charge carriers by either partial oxidation (p-doping) or partial reduction (n-doping) [10,11]. For the last three decades, a large effort has been carried out on the development of conducting polymers such as Polythiophene (PT), Polypyrrole (PPy), polyphenylene (PP), polyphenylene vinylene (PPV), polyasulfone (PS), and polyaniline (PAni) [12,13]. Figure (1.1) shows the chemical structural formula of some commonly encountered conjugated polymers [14].

Figure 1.1: Intrinsically conducting polymers [14].

These polymers because of their good electrical and optical properties have been applied in a really impressive application range in different fields such as energy storage electromagnetic interference shielding [15], light emitting diodes and photovoltaic devices, field effect transistors, plastic lasers, batteries, corrosion protection and chemical and biological sensors [16, 17].

1.5 Polyaniline (PAni)

Polyaniline (C_6H_7N) has been known for more than a century in its “aniline black” form. Among the conducting polymers, polyaniline is the most promising polymer due to its low cost, chemical stability [18], controllable electrical conductivity, excellent environmental stability, ease to synthesize through chemical or electrochemical processes and have many interesting characteristics for sensing including their high sensitivity and short response time. PAni is represented by the general following formula and structure, where B denotes a benzoid reduced unit and Q is aquinoid oxidized unit [19] as shown in Figure (1.2)

Figure 1.2: Structure of the polyaniline chain [20].

PAni is a typical phenylene-base polymer having a chemically flexible $-NH-$ group in the polymer chain flanked on either side by a phenylene ring. The protonation, deprotonation and various other physico-chemical properties of PAni can be traced to the presence of the $-NH-$ group [21]. PAni exists in various oxidation states characterized by the ratio of amine to imine nitrogen atoms [22]. When $y = 1$, the polymer is in the fully reduced leucoemeraldine (LE) state and is found to be insulating and yellow. The half oxidized polymer ($y=0.5$) is called emeraldine base (EB) and is insulating and blue. The only conducting state of PAni is the green colored emeraldine salt (ES), which is protonated form of EB [23]. Finally, pernigraniline base (PN) is the fully oxidized form of PAni ($Y= 0$) and is

insulating and purple. All these oxidation states of PANi are shown in Figure (1.3) [24].

Figure 1.3: Different oxidation states of PANi, leucoemeraldine (LE), emeraldine base (EB), emeraldine salt (ES) and pernigraniline (PN) [24].

The ability of PANi to exist in various forms via acid/base treatment and oxidation /reduction, either chemically or electrochemically, has made PANi the most tunable member of the conducting polymer. PANi was found in wide variety of applications in different fields [25]. However, PANi has a rigid backbone originating from an extended conjugated double bond [26]. The rigid structure of PANi restricts its common usage and results in the insolubility, infusibility and incompatibility of this material with common polymers. This necessitates the modification of the structure of PANi. Therefore, during the past decade researchers have directed their attention to modify PANi structure and to overcome the difficulties associated with the use of PANi by using different approaches, for example, the utilization of a soluble precursor method, in which a process able precursor polymer is first prepared in an appropriate form and then chemically converted into the final conducting polymer [27]. Another approach is the formation of conductive blends/composites [28] or the formation of PANi filled interpenetrating polymer networks. Efforts have been made to improve the properties of

PAni through the post treatment of PAni such as sulfonation or incorporation of N-alkyl sulfonic acid pendant group (the use of functional dopants and the design of self-doping polymer) [29]. Extensive studies on the polymerization of aniline (Ani) derivatives and/or the polymerization of Ani in the presence of another monomer (copolymerization) have also been carried out frequently in order to improve the properties of PAni. In recent years, due to the development of nanotechnology, PAni has been employed for studying nano composite materials in order to get new desired properties for practical application [30].

1.5.1 Different oxidation states of PAni

Unlike other known electro conducting polymers, polyaniline can exist, depending on degree of oxidation, in different forms known as: leuoemeraldine, emeraldine and perningraniline. Leuoemeraldine base refers to fully reduced form; emeraldine base is half-oxidized, while perningraniline base is completely oxidized form of polyaniline. The only conducting form of polyaniline is emeraldine salt, obtained by doping or protonation of emeraldine base [31, 32]. The unique feature of mentioned polyaniline forms is ease of its mutual conversions by both chemical and electrochemical reactions as it can be seen in Figure (1.4) [33]. Apart from the changes in oxidation levels, all the transitions among polyaniline forms are manifested by color and conductivity changes [33]. The conducting protonated emeraldine in the form of green emeraldine salt, obtained as a product of electrochemical polymerization of aniline in acidic electrolytes, can be easily transformed by further oxidation to fully oxidized dark blue perningraniline salt, which can be treated by alkali to form violet perningraniline. Emeraldine salt can also be reduced to transparent leuoemeraldine, or can be transformed by alkali to blue non conducting emeraldine. The two blue forms of polyaniline, perningraniline salt and

emeraldine have different shades of blue [33]. Both, reduction of emeraldine salt to leucoemeraldine and oxidation to perningraniline states are followed by decrease in conductivity [34].

Figure 1.4: Different forms of polyaniline [33].

1.5.2 Polyaniline Conductivity

The mechanism of polyaniline conductivity differs from other electro conducting polymers, owing to the fact that nitrogen atom is involved in the formation of radical cation; unlike most of the electro conducting polymers whose radical cation is formed at carbon. On the other hand, nitrogen is also involved in the conjugated double bonds system. Therefore, electrical conductivity of polyaniline is dependent both on the oxidation and protonation degrees [35]. As mentioned before, polyaniline is characterized by existence of various oxidation forms. Polyaniline in the form of emeraldine base can be doped (protonated) to conducting form of emeraldine salt. Emeraldine base, half oxidized form, is consisted of equal amount of amine (-NH-) and imine (=NH-) sites. Imine sites are subjected

to protonation to form bipolaron or dication (emeraldine salt form). Bipolaron is further dissociated by injection of two electrons both from electron pairs of two imine nitrogen, into quinoid imine ring, and the third double bond of benzenoid ring is formed [34]. Unpaired electrons at nitrogen atoms are cation radicals, but essentially they represent polarons. Figure (1.5) represents the polaron lattice, responsible for high conductivity of polyaniline in the form of emeraldine salt formed by redistribution of polarons along polymer chain [35].

Although both bipolaron and polaron theoretical models of emeraldine salt conductivity were proposed [36], it was lately confirmed that, beside from the fact that few of spineless bipolarons exist in polyaniline, formation of polarons as charge carriers explained high conductivity of polyaniline. Unique property of polyaniline is conductivity dependence on the doping (proton) level [35].

The maximum conductivity of polyaniline is achieved at doping degree of 50%, which corresponds to polyaniline in the form of emeraldine salt [37]. For higher doping degrees some of the amine sites are protonated, while lower doping degrees, i.e. some of the imine sites, were left un protonated [35], explaining why, in the light of the polaron conductivity model, reduction of emeraldine salt to leuoemeraldine and oxidation to pernigraniline states decrease the conductivity. The order of conductivity magnitude varies from 10^{-2} S cm⁻¹ for un doped emeraldine, up to 10^3 S cm⁻¹ for doped emeraldine salt [38].

Beside the fact that doping degree has the pronounced effect on the conductivity, other factors such as: moisture amount, morphology, temperature etc. were also found to have influence on the polyaniline conductivity[39, 40].

Figure 1.5: Schematic presentation of conductivity for polyaniline [35].

1.6 Applications of conducting polymers

Basic research and assessment of possible applications of conducting polymers all over the world show that this area is interdisciplinary in nature. Variety of technology oriented applications of conducting polymers includes electronics, optoelectronics, solar cells, semiconductors, laser, energy storage and super capacitors fields [41]. Some of these applications are as follows: Conducting organic molecular electronic materials have attracted much attention because of their many projected applications in solar cells, light weight batteries, electrochromic devices, sensors and molecular electronic devices. Polymeric heterojunctions and solar cells have been fabricated using PPy on silicon via electrochemical methods. Conducting polymers such as polyacetylene, PAni, PPy, Polythiophene, polyindole, etc. have been emerged as electrode materials in rechargeable

batteries. PPy films are applied in neurotransmitter as a drug release system into the brain. Conducting polymers have been used to fabricate diodes, capacitors, field-effect transistors (FET) and printed circuit boards (PCBs) in the field of electronics and photonics. PANi is being used as anti-static coating material for electronic storage devices, electronic boards, sensors, appliances etc. Biosensors have found promising applications in various fields such as biotechnology, food and agriculture product processing, health care, medicine and pollution monitoring [42].

1.7 Hybrids of conducting polymers

1.7.1 Introduction of Hybrids

Organic-inorganic hybrid composite (OIHC) materials are defined as “the solid materials’ composites with organic and inorganic components intimately mixed where at least one of the components domains has a dimension ranging from few angstroms to several nanometres”. Hybrid materials are defined as “mixtures of two or more materials with new properties created by new electron orbitals formed between such materials. Yamada et al. defined hybrid materials as “mixtures of two or more materials with newly formed chemical bonds” [43,44]. Hybrid materials play a major role in the development of advanced functional materials. Inorganic materials have good mechanical and thermal stability as well as optical properties; however they are hard, and brittle. Organic polymers/oligomers are flexible and generally suffer from instability to heat and tendency of natural degradation upon aging. Nevertheless, upon forming hybrid material with inorganic component, the organic moiety would provide flexibility, toughness, hydrophobicity and new electronic and/or optical properties. In principle, modification of the kind and proportions of the constituents allows an intentional tailoring of properties evolving from organic and inorganic materials [45]. Thus OIHC materials

could have desired and new features which may not be present in individual organic and inorganic components [46].

1.7.2 Classification of hybrid materials

Hybrid materials are classified into Class I and Class II based on the criteria of their chemical nature. In Class I hybrid materials, organic and inorganic components are dispersed and held together only by weak forces such as van der Waals interactions. In Class II hybrid materials, the organic and inorganic moieties are linked through strong bonds such as covalent bonds [47]. The hybrid and their related materials can be categorized into four types as follows [44]:

1. **Composites:** Mixture of materials consisting of matrix constituents at micrometer to millimeter level dispersion.
2. **Nanocomposites:** Mixture of similar kinds of materials at submicron and nano level.
3. **Hybrids:** Composites consisting of two constituents at the nanometer or molecular level.
4. **Nanohybrids:** Mixture of different materials with chemical bonds between their different materials at atomic or molecular level.

Classification of materials on the basis of different scale levels as in Figure (1.6) [48].

Figure 1.6: Classification of materials at different scale levels [48].

1.7.3 Factors influencing properties of hybrid materials

The properties of a composite product depend not only on the properties of the individual components, but also on factors such as the phase's size, shape and interfacial properties [49]. In fact, the inner surfaces predominantly play a role in deciding the properties of these hybrid materials. If the dimensions of one or both phases involved in the composite material are reduced down to the nanometer scale or even the molecular level, a synergic combination of both the constituents is possible. Properties of such nanocomposites will be different from that of classical composites, since many properties correlate with the phase dimension. Figure (1.7) depicts composites and hybrids with dimension and phases. Mixing the constituents at the microscopic scale leads to a more homogeneous material. The characteristics of this material lie either between the two original phases or even in newer properties [43].

Figure 1.7: Composites and hybrids with phases[44]

1.7.4 Synthesis of hybrid materials

There are few methods commonly used for the synthesis of hybrid materials [50]. These methods are:

1. Hydrothermal synthesis

2. Sol-gel synthesis

3. Encapsulation

4. Impregnation etc.

Hydrothermal method has been employed to grow organic, inorganic and organic –inorganic nanostructures. The hydrothermal technique is one of the most important methods for advanced materials processing, particularly owing to its advantages in the processing of nanostructured materials with a control over size and morphology properties for a wide variety of technological applications such as electronics, optoelectronics, catalysis, ceramics, magnetic data storage, biomedical, biophotonics, etc. The hydrothermal technique not only helps in processing mono dispersed and highly homogeneous nanoparticles, but also acts as one of the most attractive techniques for processing nano-hybrid and nanocomposite materials. Hydrothermal processing can be defined as any heterogeneous reaction in the presence of aqueous solvents or mineralizers under high pressure in a closed system and temperature conditions to dissolve and recrystallize (recover) materials that are relatively insoluble under ordinary conditions. Definition of the word hydrothermal has undergone several changes from the original Greek meaning of the words ‘hydros’ meaning water and ‘thermos’ meaning heat [51]

Sol-gel method is simple, low cost and yields amorphous nanocomposite hybrid materials. Hydrolysis of organically modified metal alkoxides/metal halides with/without simple metallic alkoxides in presence/absence of a specific cross linking agent yields the hybrid materials. Interactions such as hydrogen bonds, π - π interactions, van der Waals forces etc. are found between organic and inorganic components in the hybrid materials. These materials exhibit infinite microstructures and are easily shaped as films or bulks. They are generally poly dispersed in size

and locally heterogeneous in chemical composition.

In encapsulation technique, organic components get trapped during hydrolysis and condensation reactions of metal alkoxides and/or organosilanes. Organic molecules, oligomers, macromonomers and bio-components can be easily incorporated into metal oxide-based networks. This method provides heterogeneity to the organic components and thus increases life time and reuse of such precious organic components.

In impregnation method, organic components are introduced inside the porous network. Both encapsulation and impregnation methods have been extensively developed either by inorganic sol-gel chemists or by polymer chemists. Inorganic structures like silica, titania (TiO₂) and other metal oxides can function as host matrix. These amorphous composites with the control of their microstructure, exhibit a wide variety of mechanical, optical, electrical, ionic, sensor, catalytic properties [52].

1.7.5 Applications of hybrid materials

Hybridization of conducting polymers with inorganic materials has been found to improve the inherent properties of both organic and inorganic components. Thus, they open promising applications in many areas: optics, electronics, ionics, mechanics, energy, environment, biology and medicine. They are finding very high position in photovoltaic and fuel cells, photo catalysts, new catalysts, chemical/biomedical sensors, smart micro-electronic, micro-optical and photonic components etc. The practical applications of hybrid materials are many and few are listed below [53, 54]:

- a) Decorative coatings by making use of organic dyes in hybrid coatings.
- b) Scratch resistant coatings with hydrophobic or antifogging properties.
- c) Electronic and optoelectronic applications like light emitting diodes,

photodiodes, solar cells, gas sensors and field effect transistors.

d) Fire retardant materials for building construction industries.

e) Filling materials in dental treatment.

f) Electrolyte materials in solid state lithium batteries or super capacitors.

g) Antistatic / antireflection / anti corrosion coatings.

h) Porous hybrid materials for adsorption and catalytic applications.

1.8 Tin Oxides

Tin oxide (SnO_2) is a tetragonal rutile structure with lattice parameters $a=b = 4.737 \text{ \AA}$ and $c = 3.826 \text{ \AA}$ [55]. The unit cell contains two tin and four oxygen atoms. Each tin atom is bounded to six oxygen atoms at the corners of a regular octahedron, and every oxygen atom is surrounded by three tin atoms at the corners of an equilateral triangle as shown in figure (1.8) [56].

Figure 1.8: The lattice structure of SnO_2 [56].

The SnO_2 films are n-type semiconductors with a direct band gap of about (3.6- 4.3) eV. Deposition technique has strong effect on the thin film form and its structure, so it may be formed as polycrystalline or amorphous. SnO_2 semiconducting transparent thin films have various appealing features

for technical applications in solar energy conversion, flat panel displays, electrochromic devices, invisible security circuits, LEDs, gas sensing, etc. Hence large area SnO₂ films on cheap and easily available substrates are of considerable interest for the formation of most of the photonic structures [57]. Table (1.1) shows the properties of SnO₂.

Table 1.1: The properties of SnO₂ [56].

Lattice constants	a=b= 4.737 (Å), c= 3.826 (Å)
Density	6.95 (g / cm ³)
Melting point	1630 (°C)
Appearance	White powder
Crystal structure	Rutile (tetragonal)
Molecular weight	150.69 (g/mol)
Type of conductivity	n-type

1.9 Copper oxide

Copper oxide has types of polymorphism, namely, cuprous oxide (Cu₂O) and cupric oxide (CuO). These oxides are the two most important stoichiometric compounds in the Cu-O system. Both oxides are intrinsic p-type semiconductor with relatively small band gaps and show many attractive properties that can be utilized in diversity on applications. The potential applications of copper oxides include solar cells [58] Li-ion battery where they have been used as negative electrode material, superconductor, magnetic storage, gas sensors and photo-conductive

systems [59].

Cupric oxide (CuO) is an intrinsic p- type semiconductor with a band gap in the range of (1.2 -1.58) eV. The CuO has a C_2/c monoclinic crystal structure as shown in Figure (1.9) [60]. The unit cell of CuO comprises Cu^{+2} ions which are coordinated by four O^{-2} ions in an approximately square planar configuration. The abundance of its source material (Cu) together with other features such as low cost production, good thermal stability, and electrochemical properties make CuO a promising material in various applications. Furthermore, the ionicity of the Cu-O bands increases when the size of the material approached the nanodomain. This property combined with relatively large aspect ratio of CuO nanomaterials that is very attractive for applications such as gas sensing and catalyst for degradation of hazardous chemicals. Some of the important properties of CuO bulk material are given in Table (1.2).

Figure 1.9: The lattice structure of CuO [61].

Table 1.2: The properties of CuO [62].

Lattice constants	a = 0.468, b= 0.342 ,c= 0.513 (nm)
Density	6.31 (g / cm ³)
Melting point	1975 (°C)
Crystal structure	Monoclinic
Appearance	Black Powder
Molar mass	79.545 g/mol
Type of conductivity	p-type

1.10 Thin Films

The term "Thin Films" is used to describe a layer or several layers of atoms of a certain substance whose thickness ranges between (10 nm) and less than 1 μ m (1000 nm) [63]. Thin films technique is one of the most recent fully grown technologies that greatly contribute to develop the study of semiconductors and metals by giving a clear indication of their chemical and physical properties. The properties of thin films are usually different from those of the bulk because of the two dimensions nature of thin films. In bulk "three dimensions" the particles are under the influence of forces at all directions, while in thin films the forces act upon the particles at the surface only [64]. Thin films are first made by (Buser & Grove) in 1852 by using (Chemical Reaction) and later in 1857; the scientist (Farady) obtained a thin metal film by means of (Thermal Evaporation) [65]. Spray pyrolysis was first used commercially in 1947 as in U.S. patents registered for (H. A. McMaster and W. O. Lytle) to deposit conductive oxide films on heated glass substrate [66 , 67]. The film layer is deposited on certain plates chosen according to the nature of the study or the scientific need. Such plates could

be glass slides, silicon wafers, aluminum, quartz and others [63].

There are already so many applications of thin films such as the electronic and optical applications. The applications of thin films in electronics have been grown steadily in importance during the last decades, because of their use in the electronic resistances, capacitances, transistors, integral circuits for digital computers and other electronic equipments. Thin films are also particularly important for their use in great number of optical fields such as the manufacturing of ordinary and thermal mirrors, mirrors for high reflectance, semitransparent reflection coating which are used in optical devices such as filters in solar cells, and non-absorbing materials which are used for interference phenomena [67].

1.11 Thin Films Deposition Techniques

Thin films deposition techniques can be divided essentially into two main groups, namely, physical and chemical techniques [68, 69]. These techniques are shown in Figure (1.10).

1.11.1 Spin Coating Technique

Spin coating is the most widely used deposition chemical technique for the development of organic or inorganic sensing so far. Highly reproducible as well as very homogeneous films can be deposited by this technique. Two forces are acting on the solution during spin coating; the adhesive forces at the solution substrate interface and the centrifugal forces resulting from the high-speed rotation. These two competing forces will result in a strong shearing action at the interface which causes the solution to form a thin film with controllable thickness, depending on angular velocity, solution concentration and viscosity [70]. To get homogeneous films, several different factors are important and have to be considered such as evaporation rate of the solvent, viscosity of the fluid, concentration of the

solution, angular velocity (rotating speed) and spinning time.

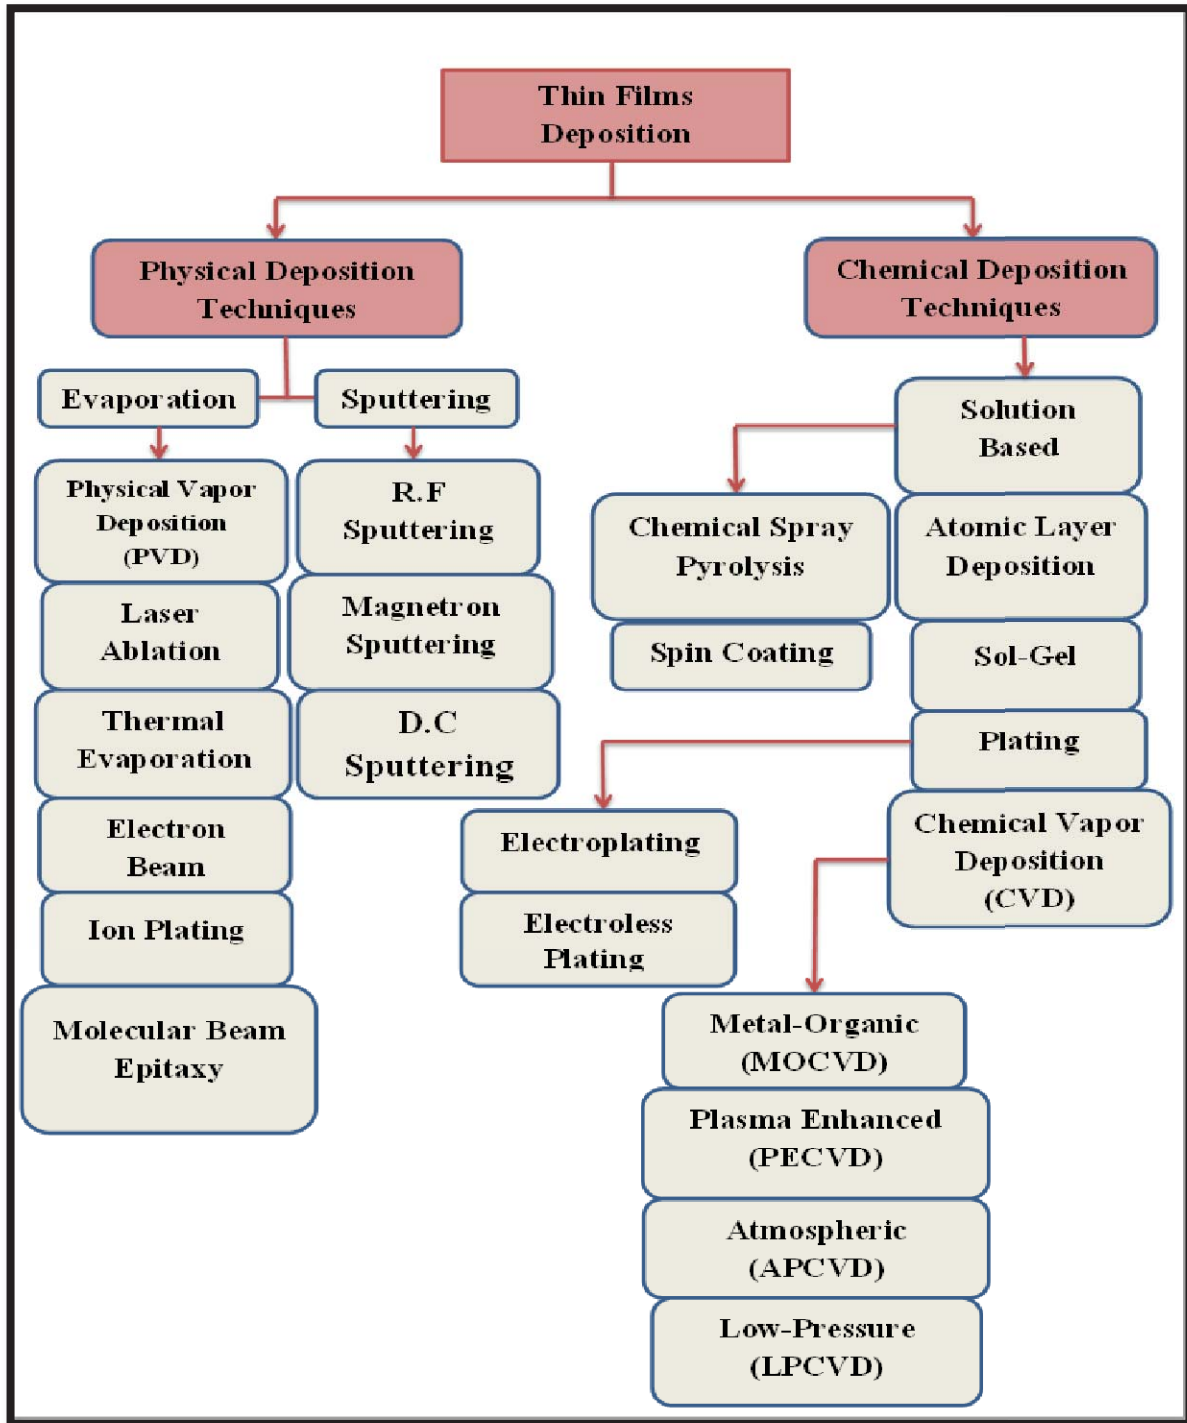

Figure 1.10: Classification of thin film deposition techniques [69].

1.12 Previous Studies

In (2004), **Bubb et al.** deposited conducting polyaniline thin films by a laser-based vaporization technique. The films have been characterized by

infrared spectroscopy, UV-Vis spectroscopy, four-point conductivity measurements, thermo gravimetric analysis, and fluorescence measurements. In addition, the films have been characterized with respect to their photoconductive response to 532nm laser light. It is found that the films exhibit persistent photoconductivity and it is proposed that defect base sequences may be responsible for the charge localization that results in such a photoconductive response [71].

In (2007), **Geng et al.** prepared a polyaniline (PAni)/SnO₂ hybrid material by a hydrothermal method and the XRD pattern suggested that PAni did not modify the crystal structure of SnO₂, but SnO₂ affected the crystallization of PAni to some extent. The gas sensitivity of the PAni/SnO₂ hybrid was also studied to ethanol and acetone at operation temperatures of 30, 60 and 90 °C. It was found that the PAni/SnO₂ hybrid material had gas sensitivity only when operated at 60 and 90 °C, and it showed a linear relationship between the responses and the concentrations of ethanol and acetone at 90 °C [72].

In (2010), **Abdolahi et al.** prepared chemically polyaniline nanofibers by an interfacial polymerization. Ammonium persulfate, hydrochloric acid and chloroform were used as oxidant, dopant and organic solvent respectively. FESEM results show that polyaniline has nanofiber morphology. XRD results show the crystalline properties of polyaniline nanofiber, and FTIR results confirmed the formation of polyaniline in different monomer/oxidant molar ratios [73].

In (2013), **Sharma et al.** fabricated ultrasonicated polyaniline (PAni) and tin oxide (SnO₂) composite nanofibers using electro spinning technique for hydrogen gas sensing application. The morphology of non-woven nanofibres with highly porous and agglomerated structure of diameter around 300-500 nm was confirmed by SEM image. FTIR and UV-Vis

spectra revealed the possible incorporation of SnO₂ in PANi and confirmed the uniform attachment of PANi on the surface of SnO₂ nanostructures. XRD pattern showed the presence of tetragonal SnO₂ and the crystalline structure of SnO₂ was not affected with the incorporation of PANi. The as-prepared nanofibers of PANi/SnO₂ nanocomposite showed improved hydrogen sensing properties at very low temperature as compared to that of pristine SnO₂ nanofibers [74].

In (2013), **Jundale et al.** prepared polyaniline (PANi) nanofibers reinforced with copper oxide (CuO) nanoparticles (NPs). The films were deposited on glass substrates by using spin coating technique. Polyaniline (PANi) have been synthesized by chemical oxidative polymerization method with monomer aniline in presence of (NH₄)₂S₂O₈ as an oxidant at 0 °C. The copper oxide (CuO) nanoparticles were synthesized by sol–gel method. Structural analysis showed that the crystal structure of CuO is not disturbed in the PANi–CuO hybrid nanocomposite. Surface morphology study shows the uniform distribution of CuO nanoparticles in PANi matrix. FTIR and UV–Vis studies confirm the presence of polyaniline in emeraldine base form in the composites and suggest incorporation of CuO in polymer. Two probe electrical resistivity measurements of nanocomposites (NCs) film revealed that the resistivity of PANi increases with increasing content of CuO NPs [75].

In (2013), **Babu1 et al.** synthesized conductive polyaniline by doping with inorganic and organic acids, namely Hydrochloric acid (HCl) and \pm 10-camphor sulfonic acid (CSA). The direct current (DC) conductivities (σ_{DC}) were found to be about 9.5×10^{-8} , 1.8, and 95.8 S/cm for PANi base, PANi (HCl) and PANi (CSA), respectively. σ_{DC} was measured down to a temperature of \sim 100 K and the apparent change in the activation energies were found to be 98.16, 74.40, and 57.24 meV for PANi base, PANi

(HCl) and PANi (CSA) respectively. σ_{DC} was less temperature dependent near room temperature, further decrease in temperature the σ_{DC} was strongly dependent. Photoluminescence (PL) peaks at 322.5, 581.4 and 644.2 nm were observed. [76].

In (2014), **Bari et al.** prepared nanocrystalline SnO₂ thin films using sol-gel dip coating technique. The starting precursor was used as tin chloride dihydrate (SnCl₂.2H₂O), ethanol and glycerin. The prepared thin films showed good selectivity to H₂ gas against LPG, CO₂, CO, NH₃, C₂H₅OH, Cl₂ and H₂S gases. It was found that the nanocrystalline SnO₂ thin films gives maximum H₂ gas response (S= 360) at 75 °C. The H₂ sensor showed fast speed of response (T_{Response}=2s) and quick recover (T_{Recover}= 8 s). The conductivity of each sample was observed to be increasing with an increase in temperature range between 50 °C and 150 °C in steps of 25 °C [77].

In (2014), **Ate et al.** synthesized CuO nanowires by thermal oxidation method. Ultrafast with high-performance CuO nanowires UV/IR photodetectors was fabricated using CuO nanowires photodetector with platinum (Pt) contact electrodes and its optoelectronic properties were examined. The results of the UV/IR photodetector exhibited a high sensitivity to UV 390 nm, Blue 410 nm ultraviolet light and 850 nm, 940 nm infrared light. The response and recovery time were also fast [78].

In (2015), **Zhu et al.** synthesized three new polyaniline (PANi) micro/nanostructures featuring square nanosheets, microspheres and micro disks via hydrothermal method. Uniform sizes and thickness of highly crystalline PANi square structural nanosheets could be tuned by the oxidative polymerization in the presence of cetyltrimethylammonium bromide (CTAB) as a template. Mechanistic studies indicate that concentrations of aniline and CTAB, reaction temperature and time had

great influence on the morphology of PANi polymers. Particularly, CTAB was essential to determine the morphology of synthetic PANi. In aqueous solution at extremely high temperature and pressure, CTAB provided various self-assembly of micelles, such as spherical micelle, planar bilayer, and lamellar phase, in which corresponding micro/nanostructures were formed. This hydrothermal fabrication gave an excellent example for the preparation of well-defined two-dimensional PANi micro/nanomaterials and potentially for other synthetic polymers [79].

In (2015), **Thenmozhi et al.** synthesized SnO₂ nanoparticles by microwave assisted solution method using SnCl₂·2H₂O as a precursor. Polyaniline doped tin oxide (PANi/ SnO₂) nanoparticles were prepared by an in situ polymerization of aniline in the presence of as-synthesized SnO₂ nanoparticles. The X-ray analysis showed that the obtained nanoparticles were SnO₂ and its crystallite size was in the range of 10-21 nm and for PANi doped SnO₂ nanoparticles, SEM micrographs indicated the presence of tin oxide nanoparticles in the PANi matrix [80].

In (2015), **Sharma et al.** synthesized and characterized polyaniline and aluminum doped tin oxide (SnO₂:Al/PANi) nanofibers for hydrogen gas sensing application. SnO₂:Al/PANi composite nanofibers had been fabricated via electrospinning technique and subsequent calcination procedure. SEM revealed the nanofibers with the diameter around 200-300 nm formed a non-woven material with highly porous and agglomerated structure. FTIR and UV-Vis spectra revealed the possible incorporation of SnO₂:Al in PANi and confirmed the uniform attachment of PANi on the surface of SnO₂:Al nanostructures. XRD showed peak broadening and the peak positions shift from standard values, indicating presence of aluminum doped tin oxide in nanoparticles form in the polyaniline (PANi) matrix. On exposure to hydrogen gas (1000 ppm), it was found that the nanofibers of

SnO₂:Al/PAni composite showed high sensitivity at 48 °C with relatively faster response/recovery as compared to pure SnO₂ and Al doped SnO₂ nanofibers [81].

In (2015), **Tomar et al.** prepared polyaniline (PAni) doped SnO₂ thin films sensors by chemical route and studied their properties towards the trace level detection of NO₂ gas. A good correlation had been identified between the microstructural and gas sensing properties of these prepared sensors. Out of those films, 1% PAni doped SnO₂ sensor showed high sensitivity towards NO₂ gas along with a sensitivity of 3.01×10^2 at 40 °C for 10 ppm of gas. On exposure to NO₂ gas, resistance of all sensors increased to a large extent, even greater than three orders of magnitude. These changes in resistance upon removal of NO₂ gas were found to be reversible in nature and the prepared composite film sensors showed good sensitivity with relatively faster response/recovery speeds [82].

In (2014), **Murugan et al.** prepared polyaniline-SnO₂ (PAni-SnO₂) hybrid materials with varied SnO₂ content by chemical oxidative polymerization method. The prepared materials were characterized by FTIR, XRD and SEM analyses. Sensitivity of the materials towards toluene was measured at room temperature from their conductivity change. The PAni-SnO₂ composite with 40 wt. % SnO₂ exhibited highest sensitivity. In situ synthesis enhanced the sensitivity of the materials over their physical mixture. This might be due to the formation of higher number of p-n heterojunctions during in situ synthesis [83].

In (2015), **Ashokan et al.** polyaniline was synthesized by chemical oxidized method and preparation of CuO nanoparticles using ethanol solvents by sol-gel route. The prepared composite samples are equal ratio of PANI/CuO (1:1) were dissolved in m-cresol solvent and were coated on glass substrate by nebulizer spray pyrolysis technique at different

temperature (100°C, 150°C and 200°C). XRD study confirms the crystalline nature of CuO peaks and shows the CuO interaction with PANi structure. The SEM study shows glouber and granular particles on the surface of PANi/CuO films. FTIR spectrum reveals that the intensity of peak is increased with the increasing temperature of the sample [84].

In (2015), **Nadaf and Venkatesh.** synthesized PANi-CuO nanocomposites by oxidative polymerization. The XRD pattern shows that the crystallization process changes with different weight percentage CuO. The degree of crystallinity increased in PANi-CuO nanocomposites with increase in weight percentage of CuO nanoparticles and clearly indicated the homogeneous distributions of nanoparticles in the polymer matrix. Morphology analysis of all the samples was done with help of SEM images [85].

In (2016), **Bhagwat et al.** synthesized (PANi) nanofibers by a facile rapid oxidative polymerization of aniline hydrochloride and ammonium persulfate at high temperature (60 °C). The XRD analysis ascertained the formation of PANi with nanocrystalline nature which showed three sharp peaks at $2\theta = 15.14^\circ, 19.36^\circ, 24.48^\circ$, which corresponds to (011), (020) and (200) crystal planes of PANi, and average crystallite size 30 nm. FTIR pattern confirmed the formation of PANi. SEM analysis had revealed homogeneous fibrous morphology of PANi nanofibers, a well formed mesh of interconnected and entangled PANi nanofibers over the scanned area. The UV-Vis spectroscopic analysis showed three major absorption peaks at 256.73, 361.17 and 480.95 nm which confirmed the PANi formation with conducting state [86].

In (2016), **Talegaonkar and Patil.** prepared nanocomposites of PANi-SnO₂ with three different molar concentrations of SnO₂ using in situ oxidative polymerization of aniline in presence of SnO₂. UV-Visible

spectroscopy of prepared samples of PANi-SnO₂ revealed emeraldine salt phase of polyaniline. XRD patterns reflect the nano crystallite size of PANi-SnO₂ composite. Transmission electron microscopic study confirms the nano-sized of prepared composite samples. Scanning Electron Microscopy of nanocomposite showed change in surface morphology with the variation in concentration of SnO₂. PANi-SnO₂ (0.25 M) nanocomposite exhibit a response to CO₂ at quit higher temperature. The effects of surface microstructure with variation in SnO₂ concentrations and surface activation with CuO on the sensor response, selectivity, recovery and long term durability of the sensor in the presence of NH₃ and other gases were studied and discussed. SnO₂ loaded PANi was outstanding in promoting the NH₃ gas sensing performance of the material. CuO as an activator in PANi-SnO₂ enhanced ammonia sensing performance of the prepared sensor samples at room temperature [87].

In (2016) **Nadaf et al.** synthesized Tin Oxide (SnO₂) nanoparticles by co-precipitation method. Aniline was polymerized in the suspension of SnO₂. Ammonium per sulphate was used as oxidizing reagent to form organic-inorganic nanocomposite materials. By this way SnO₂ nanoparticles were embedded in PANi matrix. SEM images revealed that the as-synthesized powders contained spherical particles and SnO₂ was uniformly mixed within PANi matrix. As-synthesized PANi – SnO₂ nanocomposites had been tested for gas sensing applications [88].

In (2016), **Talwar.** synthesized PANi-SnO₂ nanocomposites through chemical polymerization method. PANi-SnO₂ nanocomposites were explored for ammonia gas sensing at room temperature. These composites exhibited excellent sensor response for ammonia gas, where optimum sensor response was observed with the PANi-SnO₂ composite having 20 wt. % SnO₂ [89].

In (2017), **Sathiya et al.** synthesize copper oxide nanoparticles from various concentrations of $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$ (0.1 M - 0.5 M) precursors by using microwave assisted co-precipitation method. Both CuO and Cu_2O phases were observed from X-ray diffraction (XRD). The particle size of 43 to 27 nm determined from XRD data using Scherrer's formula was in good relation. The existence of reasonably uniform size and shape was clear from SEM. The band gap was determined from the UV-Vis absorption peaks. These results were also related to electrical conductivity at low temperatures which illustrate different types of conduction mechanisms. The samples showed semiconducting behavior with improved electrical conductivity. Finally, the material was proposed to have applications in designing gas sensors and also in regulating electrical conductivity in drug delivery systems [90].

In (2017), **Souzaa et al.** prepared a hybrid nanocomposite based on a polymer matrix constituted of Polyaniline Emeraldine-salt form (PANI-ES) reinforced by copper oxide II (CuO) particles by polymerization method. XRD technique allowed the visualization of the polymer amorphization in the nanocomposite form, suggesting an interaction between both phases. The FTIR spectra confirmed this molecular interaction due to the blue shift of the characteristic absorption peaks of PANI-ES in the nanocomposite form. SEM images revealed that the polymer nanofiber morphology was no longer observed in the nanocomposite. The CuO spherical particles are randomly dispersed in the polymer matrix. The electrical conductivity showed an increase of 60% in the nanocomposite material [91].

In (2018), **Esmaceli et al.** copper oxide- polyaniline nanofiber modified fluorine doped tin oxide (CuO/ PANi NFs/FTO) electrode is introduced as a non-enzymatic glucose sensor. PANi NFs were polymerized

by a chemical method and through a cellulose ester membrane. These fibers were dip coated on FTO and then CuO particles were deposited on PANi NFs by the electrode position method (CuO/ PANi NFs). The SEM image of Polyaniline clearly indicates that the polymer possesses nanofiber like structure According to the XRD pattern of PANi NFs , a broad peak at $2\theta \approx 20^\circ$ is related to the amorphous structure of PANi and the peaks at 26, 37, 42, 51, 61 and 66° are related to (110), (111), (200), (211), (220) and (310) miller indices of CuO crystal [92].

1.13 Objectives of the study

- 1- Synthesis of polyaniline and metal oxides (tin oxide (SnO_2) and copper oxide (CuO)) nanostructures by using hydrothermal technique.
- 2- Preparation of PANi, SnO_2 and CuO thin films, and their composites with SnO_2 and CuO thin films by spin coating technique.
- 3- Study of the mixing effect on structure, optical and electrical properties of Inorganic – Polyaniline.
- 4- Evaluation of the use of PANi, SnO_2 and CuO, nanostructure composites of PANi/ SnO_2 and PANi/CuO thin films in some optoelectronic applications such as photoconductive detector and gas sensing.
